ABSTRACT

Aims. Magnetic field of accreting neutron stars determines their overall behaviour including the maximum possible luminosity. Some models require an above-average magnetic field strength ($\gtrsim 10^{13}$ G) in order to explain super-Eddington mass accretion rate in the recently discovered class of pulsating ultraluminous X-ray sources (ULX). The peak luminosity of SMC X-3 during its major outburst in 2016–2017 reached $\sim 2.5 \times 10^{39}$ erg s⁻¹ comparable to that in ULXs thus making this source the nearest ULX-pulsar. Determination of the magnetic field of SMC X-3 is the main goal of this paper.

Methods. SMC X-3 belongs to the class of transient X-ray pulsars with Be optical companions, and exhibited a giant outburst in July 2016 – February 2017. The source has been observed during the entire outburst with the *Swift*/XRT and *Fermi*/GBM telescopes, as well as the *NuSTAR* observatory. Collected data allowed us to estimate the magnetic field strength of the neutron star in SMC X-3 using several independent methods.

Results. Spin evolution of the source during and between the outbursts and the luminosity of the transition to so-called propeller regime in the range of $(0.3 - 7) \times 10^{35}$ erg s⁻¹ imply relatively weak dipole field of $(1 - 5) \times 10^{12}$ G. On the other hand, there is also evidence for much stronger field in the immediate vicinity of the neutron star surface. In particular, transition from super- to sub-critical accretion regime associated with cease of the accretion column, absence of cyclotron absorption features in the broadband X-ray spectrum of the source obtained with *NuSTAR* and very high peak luminosity favor an order of magnitude stronger field. This discrepancy makes SMC X-3 a good candidate to possess significant non-dipolar components of the field, and an intermediate source between classical X-ray pulsars and accreting magnetars which may constitute an appreciable fraction of ULX population.

Key words. accretion, accretion disks – magnetic fields – stars: individual: SMC X-3 – X-rays: binaries

1. Introduction

Magnetic field of a neutron star (NS) defines observational properties for a broad range of systems. Strongly magnetized accreting NSs, or X-ray pulsars (XRPs), are among the most prominent NS systems and are being actively studied, particularly in connection with the possibility of super-Eddington accretion. The main source of information about the strength of magnetic fields in XRPs is associated with the so-called cyclotron scattering resonance absorption features (CSRF) observed in the energy spectra of some sources. Unfortunately, this method is restricted by a sensitivity and energy range of X-ray telescopes and relatively soft spectra of XRPs. This implies a very limited number of XRPs with known magnetic fields, all of which fall into a narrow range $B \sim (1 - 8) \times 10^{12}$ G (see review by Walter et al. 2015) defined by aforementioned selection effects. At the same time magnetic fields of very bright XRP (including the pulsating ultraluminous X-ray sources, ULXs) are expected to be $\gtrsim 10^{13}$ G (Mushtukov et al. 2015a), and it would be very important to find sources with similar fields among the ordinary accreting XRP.

Fortunately, besides the spectroscopy, pulsars timing properties can be used to independently estimate the magnetic field

strength. Accretion torque affecting the NS depend on the magnetosphere size and, although model-dependent (see, e.g., Parfrey et al. 2016), can be used to estimate the field.

Detection of a centrifugal inhibition of accretion, known as the propeller effect (Illarionov & Sunyaev 1975; Stella et al. 1986) can also be used to estimate the magnetosphere size and thus the magnetic field. The reliability of this approach has been recently demonstrated by Tsygankov et al. (2016a,b) and Lutovinov et al. (2017), who showed that the magnetic field values estimated from the propeller effect are in good agreement with measurements from independent methods (including the direct estimate based on the observed CSRF energies).

SMC X-3 was discovered with the *SAS-3* observatory as a bright source in the Small Magellanic Cloud by Clark et al. (1978). The source was reported to have a luminosity of 7×10^{37} erg s⁻¹ in the 2 – 11 keV energy band, and a relatively hard spectrum (with photon spectral index of ≈ 1). Despite of the early proposed optical identification (van Paradijs et al. 1977; Crampton et al. 1978) the nature of the source remained uncertain for a long time. Only in 2004, Edge et al. (2004) using the *Chandra* data had shown that the 7.78 s pulsar found by Corbet et al. (2004) in the *RXTE* data can be identified with

SMC X-3. Based on the precise X-ray position reported by Edge et al. (2004), Cowley & Schmidtke (2004) studied the long term optical light curve of SMC X-3 and established its counterpart as a O9e star. A number of outbursts detected with the *RXTE* observatory in 1999–2009 allowed to find a periodicity in the source activity, likely associated with the orbital motion with the period of ≈ 45 days (Corbet et al. 2004). Based on the long-term spin period evolution observed by the *RXTE*, Klus et al. (2014) estimated the expected magnetic field of the NS in SMC X-3 as $B \approx 2.9 \times 10^{12}$ G. We note that in this case a CSRF in the source spectrum at the energy of ~ 26 keV should be observable (accounting for the gravitational redshift). Another estimate of the magnetic field strength $B \approx 7.3 \times 10^{12}$ G was obtained recently by Weng et al. (2017) based on the assumption that the source was spinning close to an equilibrium in the tail of the current outburst.

Current outburst from SMC X-3 was detected with the *MAXI* monitor and was initially designated as a possible new source MAXIJ0058-721 (Negoro et al. 2016). The follow-up observations with the *Swift*/XRT telescope allowed to establish, however, that the new transient is in fact a known source (Kennea et al. 2016b), and to perform a timing and spectroscopy of this object in soft X-rays (Kennea et al. 2016a). Moreover, follow-up observations with the *NuSTAR* observatory allowed to investigate the broadband spectrum of SMC X-3 for the first time. It was shown that the SMC X-3 spectrum in the 3–50 keV energy band can be well described by an exponentially cutoff power law model with the photon index of $\Gamma \approx 0.5$ and the folding energy of $E_{\text{fold}} \approx 12$ keV. Additionally a black body component with the temperature of $kT \approx 1.78$ keV and an emission line from neutral iron with equivalent width of 70 eV were observed in the spectrum (Pottschmidt et al. 2016). It is important to emphasize that no other obvious spectral features, including the CSRF, were reported (Pottschmidt et al. 2016).

Extremely high bolometric luminosity of the source $L_{\text{peak}} \sim 2.5 \times 10^{39}$ erg s $^{-1}$, reached during this outburst, makes SMC X-3 unique among transient X-ray pulsars with Be optical companions (Be/XRPs). In fact, due to the high luminosity it can be formally attributed to the group of ULXs. Its proximity to us would make it the closest ULX in this case, and furthermore, the closest ULX-pulsar. In this work we present results of the monitoring program performed with the *Swift*/XRT and *Fermi*/GBM telescopes, as well as the *NuSTAR* observatory during recent outburst in July 2016 – February 2017. These data allowed us to estimate the magnetic field strength of the NS in the system using several independent methods and to conclude that the source likely has a non-dipole configuration of the magnetic field.

2. Observations

2.1. *Swift*/XRT data

The best facilities for long-term monitoring programs in a broad range of fluxes are currently provided by the *Swift* observatory (Gehrels et al. 2004). During the current outburst regular observations of SMC X-3 were performed with the XRT telescope (Burrows et al. 2005) in the soft X-ray band (0.5–10 keV) providing both high sensitivity and flexibility. The data analyzed in this work were collected between MJD 57611 and MJD 57785.

The XRT telescope observed SMC X-3 in both Windowed Timing (WT; providing good temporal resolution) and Photon Counting (PC) modes. Final scientific products (spectrum in

Fig. 1. The bolometric correction factor as a function of the source intensity (open circles). Filled circles show the dependence of the ratio of the total flux in 0.5 – 10 keV plus 15 – 50 keV to the 0.5 – 10 keV flux as a tracer of the bolometric correction factor (K_{bol}). Red crosses show the K_{bol} value and the source flux (in 0.5 – 10 keV range) from the broad-band spectra collected with the *NuSTAR* observatory.

each observation) were produced using online tools provided by the UK *Swift* Science Data Centre (Evans et al. 2009).¹

The spectra were grouped to have at least 1 count per bin and fitted using a simple power law model modified with the photoelectric absorption (PHABSXPPOWERLAW model in the *XSPEC* package) and Cash statistic (Cash 1979). To avoid any problems caused by the calibration uncertainties at low energies,² we restricted the spectral analysis to the 0.7–10 keV and 0.5–10 keV energy bands for the data in WT and PC modes, respectively.

We found that at all luminosities the spectra of SMC X-3 can be well described with a simple absorbed power-law model with the photon index being in the range of 0.5–1.1. The spectral analysis did not reveal any significant absorption in excess of the Galactic hydrogen column density measured in this direction $N_{\text{H}} = 0.066 \times 10^{22}$ cm $^{-2}$ (Dickey & Lockman 1990). To make the spectral approximation more robust we fixed the N_{H} value at this value. Weng et al. (2017) claimed an appearance of the black-body component at very soft energies which were ignored in our analysis.

2.2. *NuSTAR* data

The *NuSTAR* observatory consists of two co-aligned identical X-ray telescope systems (FPMA and FPMB) operating in a wide energy range from 3 to 79 keV (Harrison et al. 2013). Thanks to the unique multilayered mirrors, *NuSTAR* has an unprecedented sensitivity in hard X-rays (> 10 keV) and is ideally suited for the broadband spectroscopy of different objects, including X-ray pulsars, and searching for the CSRFs in their spectra.

SMC X-3 has been observed with *NuSTAR* twice during the current outburst (ObsIDs 90201035002 and 90201041002) with the aim of measuring its hard X-ray spectrum. Preliminary results of the analysis of the first observation were discussed above (Pottschmidt et al. 2016). The second observation was performed at our request three months later on MJD 57704.8

¹ http://www.swift.ac.uk/user_objects/

² http://www.swift.ac.uk/analysis/xrt/digest_cal.php

when the source luminosity was $\sim 1.9 \times 10^{38} \text{ erg s}^{-1}$ that is an order of magnitude lower in comparison to the first observation.

The raw observational data were processed to produce cleaned event files for the FPMA and FPMB modules using the standard *NuSTAR* Data Analysis Software (*NuSTARDAS*) v1.6.0 provided under HEASOFT v6.19 with the CALDB version 20160502. Using the *NUPRODUCTS* routine, we extracted the source spectra from the circular region with radius of $120''$. The background spectrum was extracted in the region of the same radius located $5'$ from the source position.

2.3. Bolometric correction

For any meaningful discussion of the observed source properties a bolometric correction has to be estimated for the observed flux in soft energy band. To do that we used two available *NuSTAR* observations as reference points and the dependence of the ratio of the total source flux in the $0.5 - 10 \text{ keV}$ plus $15 - 50 \text{ keV}$ energy bands to the source flux in the $0.5 - 10 \text{ keV}$ energy band. The flux in the $15 - 50 \text{ keV}$ band has been estimated using *Swift*/BAT transient monitor³ light curve of the source. The ratio $(F_{0.5-10\text{keV}} + F_{15-50\text{keV}})/F_{0.5-10\text{keV}}$ as a function of $F_{0.5-10\text{keV}}$ is shown in Fig. 1 with filled circles. To convert this ratio to the bolometric correction factor K_{bol} we rescaled it to match the values calculated from the spectral parameters obtained from two *NuSTAR* observations (marked by red crosses). The result of this adjustment shown with the open circles was fitted with a broken linear model (shown with the grey dashed line in the same figure). We estimate that residual systematic uncertainty in the correction factor does not exceed 5%. Due to unknown shape of the source broadband spectrum at low fluxes we fixed the bolometric correction factor value at 2 for all observations with $F_{0.5-10\text{keV}} < 4 \times 10^{-11} \text{ erg s}^{-1} \text{ cm}^{-2}$. In the following analysis we apply this correction to all observational data and refer to the bolometrically corrected fluxes and luminosities, unless stated otherwise.

3. Results

The light curve of SMC X-3 observed with the *Swift*/XRT telescope is shown in the upper panel of Fig. 2 with black points. The source flux was estimated using the bolometric and absorption corrections described above and assuming a distance to the source of 62 kpc (Haschke et al. 2012). The observed light curve looks rather complicated. One can see from Fig. 2 a clear transition to a faster luminosity decay after MJD ~ 57710 . This transition can be understood in terms of the thermal-viscous instability model as a moment when temperature at the outer radius of the accretion disk reached the critical temperature of $\sim 6500 \text{ K}$ causing the decrease of the local viscosity and corresponding a decline of the mass accretion rate onto the compact object (see, e.g., Lasota 2001). This results in the fast decay of the luminosity observed, particularly, from XRP in the very end of their outbursts (see recent works by Tsygankov et al. 2016a; Lutovinov et al. 2017).

As can be seen from Fig. 2 this decay is not smooth and was interrupted with temporal re-brightenings twice on MJD ~ 57730 and MJD ~ 57770 . Such behaviour of the source in the end of the outburst is likely a result of additional inflow of matter to the accretion disk during the periastron passages (shown with the green vertical dotted lines assuming the orbital ephemeris

Fig. 2. *Upper panel:* The bolometric light curve of SMC X-3 obtained with the *Swift*/XRT telescope (black points). Luminosity is calculated from the unabsorbed flux under assumption of the distance to the source $d = 62 \text{ kpc}$ and bolometric correction factors from Fig. 1. Grey dots represent flux in the $15 - 50 \text{ keV}$ band from the *Swift*/BAT monitor (in the units of mCrab, right axis). Green vertical dotted lines correspond to the times of the periastron passages. *Bottom panel:* Evolution of the photon index and ratio of fluxes $(F_{0.5-10\text{keV}} + F_{15-50\text{keV}})/F_{0.5-10\text{keV}}$ over the outburst are shown with black and blue points, respectively. Vertical dash-dotted lines correspond to the times of the *NuSTAR* observations.

reported below) and corresponding increase of the disk temperature above the critical value at the outer radius.

3.1. The broad-band spectrum

To supplement the *NuSTAR* data in soft energy band and better determine the broad band spectrum of SMC X-3 during the second *NuSTAR* observation we used the nearest in time *Swift*/XRT observation (ObsID. 00034673045). The corresponding broad-band spectrum of the source is presented in Fig. 3. The spectrum can be well approximated by the exponentially cutoff power-law with photon index of $\Gamma = 0.60 \pm 0.01$ and folding energy of $E_{\text{fold}} = 14.0 \pm 0.2 \text{ keV}$. A fluorescent iron line at the energy of $6.42 \pm 0.05 \text{ keV}$ with equivalent width of $23 \pm 5 \text{ eV}$ is also registered in the spectrum. A significantly lower value of the equivalent width in comparison to the first *NuSTAR* observation is probably due to the fixed line width at 0.1 keV in our analysis (the statistic was not good enough to determine it directly). No soft component is required for the second observation. Finally, to take into account the uncertainty in the instrument calibrations as well as the lack of simultaneity of observations by *NuSTAR* and *Swift*, a cross-calibration constants between them were included in the spectral modeling. Their best fit values of 1.024 ± 0.004 and 1.049 ± 0.015 correspond to the cross-calibrations of the FPMB module and the XRT telescope to the FPMA module, respectively.

Similar to the first *NuSTAR* observation, no other obvious spectral features (primarily, the CSRF) were found in the spectrum of SMC X-3. To quantify this conclusion we used an approach, initially proposed by Tsygankov & Lutovinov (2005) and recently improved by Shtykovsky et al. (2016). The spec-

³ <http://swift.gsfc.nasa.gov/results/transients/>

Fig. 3. The broadband spectrum of SMC X-3 (*upper panel*) measured with *Swift*/XRT telescope (green points) and two *NuSTAR* modules FPMA and FPMB (red and blue points, respectively). Black solid line represents the best fit model consisting of exponentially cutoff power-law with addition of the fluorescent iron line. Corresponding residuals to the best-fit model are shown in the *lower panel*.

trum model was modified by addition of the *GABS* component from the *XSPEC* package. The CSRF energy E_{cyc} was varied within the 6–62 keV energy range with the step of 3 keV. A corresponding line width was varied within the 4–8 keV range with the step of 2 keV. Each combination of the lines position and width were fixed and the resulting model was used to approximate the source spectrum. As a result, none of such combinations resulted in a significant improvement of the fit and only the upper limit for the optical depth of ~ 0.19 (3σ) can be obtained.

Finally, we performed also a pulse phase-resolved spectroscopy of the emission of SMC X-3 using the *NuSTAR* data. It was found that the source spectrum at different phases is well described with the same model as was used for the average spectrum. The photon index and folding energy are slightly varying with the pulse phase in the ranges of $\Gamma \sim 0.5 - 0.7$ and $E_{\text{fold}} \sim 11 - 15$ keV, respectively. Again, no indications for the CSRF were found in these spectra.

3.2. Orbital parameters

To determine the pulse frequency of the source we used the XRT window-timing mode event data which has sufficient counting statistics and time resolution. After applying the standard filtering criteria, we selected events with energies 0.3 – 10 keV from the source-centered circle with radius of 25 pixels and applied barycentric correction to the photon arrival times. To determine the spin frequency of the source for each observation we performed a search for significant peaks around the source pulse period using the H-test (de Jager et al. 1989). To estimate the uncertainty of the obtained value we used the same approach as Markwardt et al. (2002), i.e. assumed that one sigma uncertainty for the most significant frequency peak in periodogram corresponds to the drop $\Delta Z^2 = 1$ with respect to the peak value. The results are presented in Fig. 4 and are consistent with values reported by *Fermi*/GBM pulsar project,⁴ (Townsend et al. 2017; Weng et al. 2017).

Note that modulation of the pulse frequency associated with the orbital motion is apparent and has to be taken into the account when determining the intrinsic spin frequency of the NS.

Table 1. Best-fit orbital parameters of SMC X-3.

Parameter	Value
Orbital period (d)	45.07(5)
$a_x \sin i$ (light seconds)	189(1)
e	0.231(6)
ω (degrees)	206(2)
T_ω (MJD)	57631.5(2)
χ^2/dof	117.2/91

Note: Parameters are based on the full sample of the *Fermi*/GBM and *Swift*/XRT data. Uncertainties are quoted at 1σ confidence level including the model systematics. The fit statistics for the same parameters without inclusion of the model systematics is $\chi^2 = 3992$ for 91 dof.

The parameters of the binary orbit were estimated for the current outburst by Townsend et al. (2017) and Weng et al. (2017), however, both works only use a subset of the available data, and are not fully consistent with each other. The discrepancies, particularly in the obtained orbital period value, likely arise due to the difficulties in modeling of complex intrinsic spin evolution of the source.

To obtain an improved orbital solution we followed the approach similar to that by Townsend et al. (2017), i.e. estimated the intrinsic spin frequency of the pulsar based on the expected accretion-induced spin-up. We note that angular momentum transferred to the NS by the accretion disk is proportional to the accretion rate and thus is expected to dominate the spin evolution of the NS at high luminosities. The details of interaction of the disk with the magnetosphere are not thus very important and it is sufficient to consider only the accelerating torque (which, however, still depends on the magnetosphere size) with the spin-up rate defined as (Lipunov 1982)

$$\dot{\nu} = \dot{M} \sqrt{GMR_d} / 2\pi I, \quad (1)$$

where the inner disk radius $R_d = kR_A$ is assumed to constitute some fraction of the Alfvénic radius, and I is NS moment of inertia. Note that this is essentially the same model as used by Townsend et al. (2017). The main difference is that we use the bolometric light curve rather than flux in the soft band to estimate the accretion rate $\dot{M} = R_{\text{NS}} L_X / GM$. Another difference is that we include also the spin frequency measurements reported by *Fermi*/GBM into the fit to improve statistics. Finally, Townsend et al. (2017) do not account for the model systematics associated with the fact that uncertainties in the observed accretion rate inevitably translate to a systematic uncertainty in the predicted frequency when integrating over the outburst. On the other hand, this uncertainty can be easily estimated directly from the dispersion of model predictions for a set of light curves simulated based on the observed fluxes and uncertainties (once initial estimate for R_d is obtained). We estimated the model systematics to increase from zero at the beginning of the outburst to $\sim 2 \times 10^{-6}$ Hz at the end of the outburst, and added it in quadrature to the statistical uncertainties to obtain the final fit and estimate the uncertainties for the orbital parameters presented in Table 1. Note that using the bolometric light curve allows to obtain a much better fit than reported by Townsend et al. (2017)

⁴ <https://gamma-ray.nsstc.nasa.gov/gbm/science/pulsars/lightcurves/sum3.html>

Fig. 4. Spin evolution of SMC X-3 as observed by *Fermi*/GBM and *Swift*/BAT (black points), and the best-fit models for intrinsic (red) and observed (blue) pulse frequencies. Residuals for the best-fit model are also shown in the bottom panel.

4. Discussion

4.1. Critical and maximal luminosities

In the case of very strong magnetic field Compton scattering cross section is strongly reduced (see, e.g., Mushtukov et al. 2016). This reduces an impact of the radiative pressure and was shown to be required to allow the accreting X-ray pulsar to exhibit super-Eddington luminosities during giant outbursts similar to one observed from SMC X-3. Particularly, it is possible due to the rise of the accretion column above the NS surface (Basko & Sunyaev 1976; Mushtukov et al. 2015b). Critical luminosity L^* dividing two regimes of accretion is a function of the magnetic field strength in the vicinity of the NS surface. Therefore, observational constraint of L^* can be used to obtain independent estimates of the magnetic field. It is worth to note here that observational evidence of a transition through the critical luminosity was recently found in the classical XRP V 0332+53 (Doroshenko et al. 2017).

It is interesting that SMC X-3 exhibits a substantial change of its pulse profile between MJD ~ 57680 and MJD ~ 57700 when its main peak shifted by $\sim \pi/2$ (see Fig. 4 in Weng et al. 2017). We argue that this change happens when the bolometric luminosity of the source was $\sim (2-3) \times 10^{38} \text{ erg s}^{-1}$ is caused by the disappearance of the accretion column and corresponding modification of the intrinsic X-ray beaming from the pulsar (Gnedin & Sunyaev 1973). Interpretation of this luminosity as a critical one results in the estimates of the magnetic field of $B \simeq (2-3) \times 10^{13} \text{ G}$ (Mushtukov et al. 2015b).

Maximal accretion luminosity of the NS depends on the magnetic field strength as well (Mushtukov et al. 2015a). The bolometric peak luminosity of SMC X-3 achieved during the 2016–2017 outburst is $\sim 2.5 \times 10^{39} \text{ erg s}^{-1}$ exceeding the Eddington limit by an order of magnitude. According to the accretion column theory by Mushtukov et al. (2015a) so high luminosity is impossible if the NS magnetic field is less than $\sim 2 \times 10^{13} \text{ G}$. This value agrees well with the one derived above from the critical luminosity. Both methods refer to the magnetic field strength in the region of the main energy release, i.e. in immediate vicinity of the NS surface.

4.2. Accretion torque

Evolution of the intrinsic spin frequency of accreting pulsars is driven by angular momentum transfer from the accretion disk, and possibly by braking mechanisms associated with interaction of the magnetosphere with the disk (Ghosh & Lamb 1979; Wang 1987; Lovelace et al. 1995; Parfrey et al. 2016). In case of SMC X-3, however, the accelerating torque is expected to dominate, and indeed, as already mentioned in Section 3.2, no evidence for braking has been observed. The observed spin evolution is thus fully consistent with pure spin-up by the disk which is trivial to calculate and allows to estimate the magnetic field. As follows from Eq. (1), the magnetosphere size or, equivalently, magnetic field strength of the NS is one of the model parameters that can be obtained during the fit of the orbital parameters if physical parameters of the NS and relation of the inner disk and Alfvénic radii are known or assumed. For standard NS with mass and radius of $1.4M_{\odot}$ and 10 km respectively, and coupling factor $k = 0.5$ the field strength is well constrained at $B = 2.55(1) \times 10^{12} \text{ G}$. This is consistent with the value reported by Klus et al. (2014) based on the spin evolution between outbursts, and an order of magnitude lower than estimated above based on the observed critical and maximal luminosities.

4.3. Propeller effect

The distinctive property of accretion onto the highly magnetized NS is a strong centrifugal barrier produced by the rotating magnetosphere. This barrier does not allow the accreting matter to penetrate into the magnetosphere if the velocity of the field lines is higher than corresponding local Keplerian velocity, that is known as propeller effect (Illarionov & Sunyaev 1975; Stella et al. 1986). In other words the accretion is only possible if the magnetospheric radius R_m does not exceed the co-rotation radius R_c .

Because the magnetospheric radius depends on the mass accretion rate, we can link the transition luminosity L_{lim} with the spin period of the NS and its magnetic field strength. The corresponding equation can be derived by the equating the magnetospheric radius to the co-rotation radius (e.g., Campana et al. 2002):

$$L_{\text{lim}}(R) \simeq \frac{GM\dot{M}_{\text{lim}}}{R} \simeq 4 \times 10^{37} k^{7/2} B_{12}^2 P^{-7/3} M_{1.4}^{-2/3} R_6^5 \text{ erg s}^{-1}, \quad (2)$$

where P is the NS spin period in seconds, B_{12} is the strength of the dipole component of the magnetic field in units of 10^{12} G , $M_{1.4}$ and R_6 are the NS mass and radius in units of $1.4M_{\odot}$ and 10^6 cm , respectively. A factor k relates the magnetospheric radius to the classical Alfvén radius in the case of disc accretion and is usually taken $k = 0.5$ (Ghosh & Lamb 1978).

On 2017 February 1, SMC X-3 was still very bright to expect the transition to the propeller regime for the NS with standard magnetic field. Therefore, we investigated the archival *Swift*/XRT and *Chandra* data. The archival *Swift* observations were analysed as described above. The source spectra available as part of the *Chandra* Source Catalog⁵ were fit using the *xspec* and the same model as for the *Swift*/XRT spectra. The resulting light curves based on all available data as well as 3σ upper limits are shown in Fig. 5.

From Fig. 5 one can see that SMC X-3 was significantly detected at low luminosities during several type I outbursts. The faintest state of the source with bolometric luminosity of

⁵ <http://cxc.harvard.edu/csc/>; Evans et al. (2010)

Fig. 5. The bolometric light curve of SMC X-3 as seen by the *Swift*/XRT telescope obtained during giant outburst in 2016–2017, type I outbursts in September–October 2010, August–November 2012 and March 2014 are shown with black circles, red circles, green squares and blue triangles, respectively. *Chandra* measurement from April 2006 is represented with magenta square. The 3σ upper limits are shown with arrows of the corresponding color. The historical data were shifted by an integer number of the orbital periods obtained in the current work (see Table 1) for illustrative purpose. The luminosity is calculated from the unabsorbed flux under assumption of the distance to the source $d = 62$ kpc and bolometric correction factors from Fig. 1. The horizontal dashed lines show the upper and lower limits for the threshold luminosity for the propeller regime onset (see the text). Green vertical dotted lines correspond to the times of the periastron passages.

$\sim 3.5 \times 10^{34} \text{ erg s}^{-1}$ was observed by the *Chandra* observatory on 2006, April 26. Just one day before that the source was not detected with 3σ upper limit of $\sim 2.5 \times 10^{33} \text{ erg s}^{-1}$. The lowest significant luminosity of SMC X-3 can serve as an estimate for the threshold of the propeller regime onset $L_{\text{lim}} \sim 3 \times 10^{34} \text{ erg s}^{-1}$. On the other hand, based only on the *Swift*/XRT data the limiting luminosity can be as high as $L_{\text{lim}} \sim 7 \times 10^{35} \text{ erg s}^{-1}$. Therefore, we use here very conservative range of luminosities from $\sim 3 \times 10^{34} \text{ erg s}^{-1}$ to $\sim 7 \times 10^{35} \text{ erg s}^{-1}$ to estimate the dipole component of the magnetic field (shown by horizontal dashed lines in Fig. 5). Substituting the measured spin period of SMC X-3 ($P = 7.81$ s) and the range of limiting propeller luminosity L_{lim} to the Eq. (2) and assuming the standard mass and radius of the NS we can estimate the dipole component of the NS magnetic field as $B \sim (1 - 5) \times 10^{12} \text{ G}$.

Interestingly, both methods (accretion torque and the propeller effect) measuring the dipole component of the magnetic field well agree with each other and give significantly lower strength in comparison to the methods sensitive to the magnetic field in the vicinity of the NS (critical and maximal luminosities, absence of the CRSF). This fact can point to the strongly non-dipole configuration of the NS magnetic field with multipoles by an order of magnitude stronger than dipole component within the emission region. Another possibility to resolve this discrepancy is significant deviation of the parameter k from the standard value of 0.5 adopted in our study. Namely, the estimate of the dipole component of the magnetic field B_{dipole} will coincide with multipole component $B_{\text{multipole}}$ for $k \approx 0.15$.

However, this assumption seems to be inconsistent with the results obtained previously for other sources. Indeed, up to date the propeller effect was observed in SAX J1808.4–3658 (Campana et al. 2008), GRO J1744–28 (Cui 1997), 4U 0115+63

Fig. 6. Correlation between a combination of the propeller limiting luminosity and the pulsar spin period, $L_{\text{lim}} P^{7/3}$, and independently determined magnetic field strength B for six pulsating sources (black squares; adopted from Tsygankov et al. (2016a)). Dashed line represents the theoretical dependence given by Eq. (2) for $k = 0.5$. Estimate of the limiting luminosity and corresponding dipole field strength for SMC X-3 are shown with horizontal shaded region and dotted vertical lines, respectively. The solid red vertical line indicates the dipole field estimate from the observed spin evolution of the source. Constraints on the field strength in vicinity of the NS based on the observed critical and maximal luminosities and CRSF non-detection are shown with vertical shaded region. Note an order of magnitude discrepancy between the field estimates at the magnetosphere and in vicinity of the NS.

(Tsygankov et al. 2016a), V 0332+63 (Tsygankov et al. 2016a), SMC X-2 (Lutovinov et al. 2017), and the accreting magnetar M82 X-2 (Tsygankov et al. 2016b). All these sources are collected in Fig. 6 where the combination of the propeller limiting luminosity and corresponding pulse period, $L_{\text{lim}} P^{7/3}$, are compared with magnetic field strength measured independently (mainly based on the observed CRSF energy, see Tsygankov et al. 2016a, and references therein). Note that for all six sources the limiting luminosity seems to agree with the theoretical dependence given by Eq. (2) for $k = 0.5$ shown with dashed line.

5. Conclusion

In this paper we report the estimate of the magnetic field strength in a bright X-ray pulsar SMC X-3 which can be considered the closest ULX-pulsar. The source exhibited a giant outburst in July 2016 – February 2017 with the peak bolometric luminosity of $\sim 2.5 \times 10^{39} \text{ erg s}^{-1}$. The entire outburst had been monitored with the *Swift*/XRT and *Fermi*/GBM telescopes, as well as with the *NuSTAR* observatory. The collected data allowed us to estimate the magnetic field strength of the NS in SMC X-3 using several independent methods based on the spectral and timing properties of X-ray emission from the system.

The dipole component of the magnetic field was determined using the accretion torque models and observation of the transition to the propeller regime at the limiting luminosity in the range of $\sim (0.3 - 7) \times 10^{35} \text{ erg s}^{-1}$ both resulting in relatively weak strength of about $(1 - 5) \times 10^{12} \text{ G}$. On the other hand, there is evidence for a much stronger field strength in the immediate vicinity of the NS surface. In particular the transition from super-

to sub-critical accretion regime associated with cease of an accretion column and very high peak luminosity favor the magnetic field of $\sim (2 - 3) \times 10^{13}$ G. Absence of the CSRF in the broad-band X-ray spectrum of the source obtained with *NuSTAR* is also consistent with this estimate.

This discrepancy makes SMC X-3 a good candidate for a NS with strong multipole configuration of the magnetic field, and an intermediate source between classical X-ray pulsars and accreting magnetars which may constitute an appreciable fraction of ULX population. Alternatively, this discrepancy can be resolved if one assumes that the accretion disc in SMC X-3 pushes much deeper into magnetosphere than normally expected. However, the reason for such behaviour would be unclear as it was not observed in other objects with wide range of luminosities for which similar analysis was conducted.

On the other hand, existence of higher field multipoles was also claimed for pulsating ULX-1 in NGC 5907 (Israel et al. 2016). One can thus speculate that a complex structure of the NS magnetic field may thus be a common feature for this class of objects.
